Symptomatic spinal cord metastasis of glioblastoma multiforme

Metástase espinhal sintomática de glioblastoma multiforme

ABSTRACT
Symptomatic spinal cord metastasis from glioblastoma multiforme (GBM) has rarely been reported in the literature. We report the case of a 27-year-old man who presented with back and bilateral leg pain nine months after the primary diagnosis of intracranial GBM. A magnetic resonance imaging (MRI) of the lumbar spine showed a L1-L2 tumor that was removed successfully and histopathological examination was consistent with GBM metastasis. Spinal metastasis should be investigated and included in the differential diagnosis in a patient with a previous history of intracranial GBM presenting with spinal symptoms.

Key words: glioblastoma multiforme, symptomatic spinal metastasis, lumbar region.

SUMÁRIO
Metastasis espinhais sintomáticas de glioblastoma multiforme são raramente descritas na literatura. Relatamos o caso de um paciente de 27 anos que apresentou quadro de dor lombar e em membros inferiores bilateralmente nove meses após diagnóstico de GBM intracraniano. Exame de ressonância magnética da coluna lombar mostrou tumor em L1-L2 que foi removido com sucesso, e análise anatomopatológica foi consistente com metástase de GBM. Metástase espinhal deve ser investigada e incluída no diagnóstico diferencial de paciente com história prévia de GBM intracraniano e queixa de sintomas espinhais.

INTRODUCTION

Glioblastoma multiforme is the most frequent primary brain tumor in adults, representing near 15-20% of all intracranial neoplasms and 50% of astrocytomas. There is a male predominance and the peak age is 45 to 60 years. Despite advance in early diagnostic imaging, microsurgical techniques and complementary therapies, patients with GBM have a median survival of 12 months. Symptomatic spinal cord metastases from brain GBM is a rare find due the fast progression of this neoplasm and given that subarachnoid dissemination usually occurs tardily. We describe a rare case of symptomatic GBM metastasis to the spine and discuss the presentation of symptoms, mechanism of metastasis and treatment options.

CASE REPORT

A 27-year-old man was admitted to the hospital with a history of continuous and progressive headache. On examination, there were no focal neurologic deficits and he was otherwise neurologically intact. Computed tomography (CT) and contrast-enhanced MRI revealed a 3 cm mass lesion with significant vasogenic edema located in the right frontal lobe. A partial surgical resection was performed and histopathological studies showed glioblastoma multiforme (WHO grade 4). Postoperatively, irradiation of the whole brain was started and he received temozolamide as concurrent chemotherapy. Six months after surgery, he was admitted to the emergency room with a history of seizure and nausea. CT and MRI demonstrated an enlargement of the tumor and significant midline shift. A gross total resection was performed and the patient evolved with good neurological conditions. Nine months after the primary diagnosis, the patient returns to the emergency room complaining of severe and persistent bilateral leg pain radiating from back that progressively got worse and urinary dysfunction. Physical examination reveals decreased pinprick sensation and numbness over both lateral legs. The patient was evaluated as having a possible herniated disc or spinal stenosis, but lumbar MRI revealed a contrast-enhanced intradural extradural mass at the level of the L1-L2 vertebral body. The lesion measured 2.7 cm in its craniocaudal dimension with an anteroposterior dimension of 1.5 cm (Fig. 1 and 2). The patient underwent a L1-L2 laminectomy with microsurgical resection of the tumor: the tumor compressed the nerve roots, with anterior dislocation of the cauda equina. Histopathological and immunohistochemical examination was consistent with GBM (Fig. 3). Significant relief of pain and improvement of urinary dysfunction was observed in postoperative period.

Spinal glioblastoma metastasis can be found often in post-mortem studies, but symptomatic case like this is rare in the literature. Autopsy series revealed an intramedullary and leptomeningeal metastasis incidence of up to 20% in cases of intracranial GBM. The rate of symptomatic spinal metastasis was about 2% in a large series with 600 patients with GBM, and a single institution study reports only 1.1% of 267 patients harboring a glioblastoma presenting with spinal metastasis.

A recent meta-analysis revealed 19 cases of adult patients with previous diagnosis of intracranial glioblastoma harboring a symptomatic spinal metastasis. In this review, symptomatic spinal metastasis was leptomeningeal in 66.7% of the cases. The mean age of the patients at time of diagnosis was 45 years, considerably younger than the mean age of presentation described in literature for intracranial GBM.

The lumbosacral spine is the most common site for glioblastoma spinal metastasis, followed by thoracic and cervical region. This can reflect the effects of gravity and the natural flow of cerebrospinal fluid (CSF).

There is a discussion in the literature regarding the origin of spinal metastasis. There are few articles reporting spinal metastasis in patients without previous brain surgery or radiation therapy compared to a number of cases describing patients with spinal metastasis after cranial operation or irradiation. This supports the thesis that surgical manipulation or radiation therapy can alter the blood-brain barrier and spread the tumor cells by hematogenous dissemination or directly through the subarachnoid space. However, a study shows that the contact of the intracranial tumor with the CSF by the opening of the ventricles during surgery or just by the primary site of location seems not to be a precondition for dissemination of the gliomas.

The extent in survival time due to advances in the treatment of gliomas and the modern diagnostic techniques have increased the report of symptomatic metastasis cases of intracranial gliomas. Spinal leptomeningeal metastasis produces a constellation of symptoms. These may include focal back pain, radicular pain, numbness, paraparesis, sphincter dysfunction, and other symptoms referable to the intracranial tumors such headache, seizures and nausea. Neurosurgeons, oncologist and clinicians who treat high grade gliomas should be aware of such a manifestation.

In brazilian literature there are very few publications concerning spinal cord metastatic glioblastoma multiforme. We only found a single case describing an eleven years-old girl with a right tempo-parietal glioblastoma multiforme that metastasised to the caudal portion of the spinal canal after cranial resection and radiotherapy. Another case reported a lumbar vertebral metastasis presented with back pain in a patient harboring a right cerebral glioblastoma.

Taking into consideration that the treatments goals are not the cure, radiotherapy is the most usual choice of treatment modality. Surgical decompression is not considered as a first treatment option since is not superior in improving quality of life compared to other treatment modalities. The advantage of surgical resection is the possibility of hystopathological examination in the lack of previous craniotomy and unknown primary brain tumor, and to achieve rapid pain control by decompression.

Stereotactic radiosurgery (SRS) can be an effective option in the treatment of spinal metastasis and reduction of local pain. In SRS, a target is localized using three-dimensional image guidance and a high-energy radiation dose is delivered, minimizing the damage to the spine and surrounding structures. Some series report a pain relief in near 90% of patients after treatment. Compared with open surgery, it has the advantage of lower cost and less postoperative complications.

In conclusion, spinal metastasis should be investigated and included in the differential diagnosis if a patient with a previous history of intracranial GBM presents with radicular and/or back pain and other spinal symptoms.
